Abstract: A pulse oximeter model linking arterial (SaO₂) and peripheral (SpO₂) oxygen saturation is the terminal part of a mathematical model of neonatal oxygen transport. Previous studies have confirmed the overestimation of oxygen saturation measured by pulse oximetry in neonates compared to arterial oxygen saturation and the large variability of measured values over time caused by measurement inaccuracies. This work aimed to determine the SpO₂ measurement noise that affects the biased SpO₂ value at each time point and integrate the noise description with the systematic bias between SaO₂ and SpO₂. The SaO₂–SpO₂ bias was based on previously published clinical data from pathological patients younger than 60 days requiring ventilatory support. The statistical properties of the random SpO₂ measurement noise were estimated from the SpO₂ continuous recordings of 21 pathological and 21 physiological neonates. The result of the work is a comprehensive characterization of the properties of a pulse oximeter model describing the transfer of the input SaO₂ value to the output SpO₂ value, including the bias and noise typical for the bedside monitoring of neonates. These results will help to improve a computer model of neonatal oxygen transport.

1. Introduction

The advantages of closed-loop control of oxygenation in neonates compared to manual control have been documented in recently published clinical trials. During automatic control, arterial blood oxygen saturation remains within the desired safe range for significantly longer periods [1–6]. In the last ten years, many articles have introduced closed-loop control algorithms of oxygenation in neonates, but a complex clinical study to compare the effectiveness of those various algorithms is still missing [6]. Clinical tests of the new oxygenation control algorithms of neonates bring safety and ethical risks, but a mathematical model of oxygenation in neonates can allow for the in silico simulation of oxygenation and preliminary comparison of the control algorithms [7–10].

A general scheme of a complex mathematical model of automatic oxygenation of a neonate is shown in Figure 1. The terminal part of the model is the pulse oximeter module. In the absence of arterial blood gas measurement, both the automatic and manual control of oxygenation usually depend on pulse oximetry [1,7,11]. Many studies showed inaccuracies in the pulse oximetry measurement in children and premature infants. Peripheral oxygen saturation measured by pulse oximetry (SpO₂) typically overestimates arterial oxygen saturation (SaO₂), especially at the lower values of SaO₂ that are common in critically ill premature infants and children. Bohnhorst et al. noted the presence of the SaO₂–SpO₂ bias in Reference [12], where the authors determined the sensitivity

and specificity of different pulse oximeters in the detection of hyperoxemia in 56 infants. Gerstmann et al. [13] found that SpO_2 generally overestimated SaO_2 at low levels and that the spread in the data increased with lower SaO_2 . The results were confirmed a few years later by Rosychuk et al. [14] in neonates with an average weight of 1 kg. The authors used a new generation of pulse oximeters with lower susceptibility to motion artifacts. Harris et al. [15] evaluated two sensors with improved accuracy in children with SaO_2 less than 85%. This study revealed statistically significant increasing bias and variability of SpO_2 for decreasing levels of SaO_2 and the authors concluded that pulse oximetry alone should not be relied upon for clinical decision-making when saturation is below 85%. In another study, Harris et al. [16] confirmed their previous findings and set the average bias at 4.0% and 7.4%, respectively, depending on the type of pulse oximeter. A similar average bias of 5.4% across all saturation levels was found by Murphy et al. [17] in a study of 89 patients with critical congenital heart disease. Ross et al. [11] described a significant variation in the SpO_2 accuracy. The authors computed the SaO_2 – SpO_2 bias (0.2–6.6%) and precision (3.4–6.6%), expressed as the standard deviation, for seven intervals in the range of 65–97% SpO_2 in 225 mechanically ventilated children with cyanotic congenital heart disease or acute hypoxemic respiratory failure. Very similar results were provided in the study of Bachman et al. [18] by evaluating 25 032 SaO_2 – SpO_2 measurements from 1007 critically ill neonates, or in the study of Griksaitis et al. [19] in 25 children with cyanotic congenital heart disease.

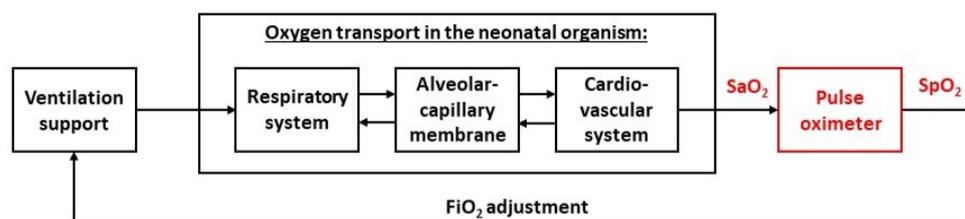

Figure 1. A general concept of the mathematical model of neonatal oxygen transport. The pulse oximeter module, with arterial oxygen saturation (SaO_2) as the input and peripheral oxygen saturation (SpO_2) as the output, is the terminal part of the global model.

Several studies [11,13–15,18] pointed out not only the bias between SaO_2 and SpO_2 (SaO_2 – SpO_2 bias) but also quite a large variability in the bias. This variability can be caused by many factors that affect the accuracy of the pulse oximeter measurement. In the multicenter study [11], the variability in the bias could have been caused by institutional variation, for example, by using pulse oximeters from different manufacturers. A location of probe placement can influence measured SpO_2 values [11,20,21]; however, Harris et al. [15] did not show a significant difference between standard and nonstandard probe location. The studies [11,18] involved premature infants who could have had increased levels of fetal hemoglobin (HbF) that may alter the SaO_2 – SpO_2 bias [11,14,20,22]. In addition to HbF, other hemoglobin derivatives, such as carboxyhemoglobin or methemoglobin, may also affect the accuracy of the measurement [21,22].

Besides the interpersonal variability, experimental data also contain intrapersonal variability in time. A low pulsatile signal (low perfusion), high noise (bright light, electromagnetic interference, or motion), or a combination of these factors can cause a low signal-to-noise ratio, leading to inaccurate pulse oximeter readings [21,23,24]. Even when SaO_2 remains practically unchanged, the SpO_2 values presented by the pulse oximeter change in time, and in the case of abrupt motion of a neonate, they may even be falsely interpreted as rapid desaturations [23].

Recent studies dealing with noise and its filtering in relation to pulse oximetry focused on the photoplethysmography curve used by pulse oximeters. Fine et al. [25] summarized several ways of detecting noise or motion artifacts, which included using the low-signal-quality index, filters with cross-correlation, analyzing the morphology of the signal, or higher-order statistics in both the frequency and time domain. Lee et al. [26] proposed

a motion artifact reduction algorithm, using independent component analysis. Other studies [27,28] assessed the quality of SaO₂ estimation from photoplethysmography and detected poor-quality segments by methods of machine learning. However, the considered global model of neonatal oxygenation [8] does not consider the pulsatility in the cardiovascular system and, thus, the photoplethysmography curve. Instead, the pulse oximeter module is treated as a black box that converts a continuous SaO₂ signal to a stream of trend SpO₂ values, reported every 2 s, that is used by automatic closed-loop control algorithms to adjust the fraction of inspired oxygen in the model input. A pulse oximeter model transforming SaO₂ to the observed SpO₂ value was used by Morozoff et al. [29]. The model adds two types of noise to the SaO₂ signal: the sensor noise modeled as the white noise and motion artifacts produced by a pulse generator. However, this approach is not based on real data from clinical practice.

The aim of this work was to statistically describe the SpO₂ measurement noise characteristic of continuous time recording of SpO₂ based on the evaluation of available clinical data and to combine the noise description with the systematic bias between SaO₂ and SpO₂ into a plausible mathematical model of the pulse oximeter output signal. The results of the work were intended for integration into an overall computer model of premature infant oxygenation.

2. Materials and Methods

The input of the pulse oximeter module of the overall oxygenation model is the continuous SaO₂ signal. The output signal of the pulse oximeter module consists of two principal components: the SaO₂–SpO₂ bias and the SpO₂ measurement noise. The SaO₂–SpO₂ bias describes a typical deviation of the SpO₂ measurement as a function of SaO₂ value. The SpO₂ measurement noise is a random process that changes the biased SpO₂ value at each time point. Data for both the components of the pulse oximeter model were processed in Matlab R2021a (MathWorks, Natick, MA, USA).

2.1. SaO₂–SpO₂ Bias

The SaO₂–SpO₂ bias function was determined in our previous study [30] based on clinical data acquired by Ross et al. [11]. We used the part of the data that included mechanically ventilated hypoxemic premature and term infants aged between the 37th week of gestation and the 60th day after delivery. We evaluated 1423 SaO₂–SpO₂ data pairs. The SaO₂ values were measured by CO-oximetry, and the SpO₂ values were measured by Masimo or Nellcor pulse oximeters at the same time the arterial blood sample was taken. We calculated the bias in three neighboring intervals. For SaO₂ below 70%, the SpO₂ bias was kept constant and equal to the 7.66%, which was the SpO₂ bias at SaO₂ = 70%. For SaO₂ in the range of 70–96%, the median of measured SpO₂ values was calculated for each unit value of SaO₂ and a third-order polynomial was fitted through the medians. For SaO₂ above 96%, the bias was set as zero, that is, SpO₂ = SaO₂. The SaO₂–SpO₂ bias function is displayed in Figure 2 and mathematically expressed by the following equations:

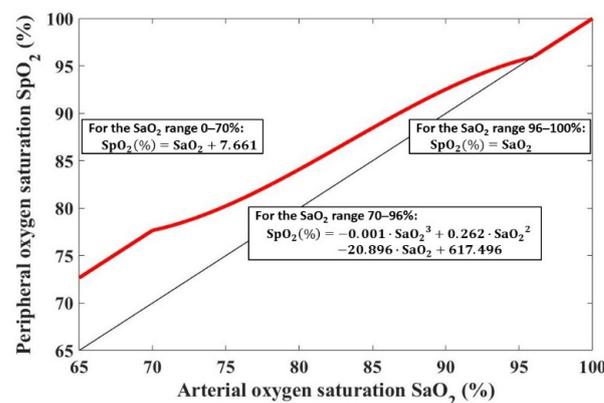

Figure 2. The SaO₂–SpO₂ bias function is shown with a red line. The black line shows SpO₂ = SaO₂.

- For the SaO₂ range 0–70%:

$$\text{SpO}_2(\%) = \text{SaO}_2 + \text{SpO}_2^{(\text{SaO}_2=70\%)} = \text{SaO}_2 + 7.66$$

- For the SaO₂ range 70–96%:

$$\text{SpO}_2(\%) = -0.001 \cdot \text{SaO}_2^3 + 0.262 \cdot \text{SaO}_2^2 - 20.896 \cdot \text{SaO}_2 + 617.496$$

- For the SaO₂ range 96–100%:

$$\text{SpO}_2(\%) = \text{SaO}_2$$

2.2. SpO₂ Measurement Noise

We based the model of SpO₂ measurement noise on continuous neonatal SpO₂ recordings from the General University Hospital in Prague. The data were collected during routine clinical care, based on a standard informed consent to hospitalization and to collection of anonymous observational data for research and educational purposes that was signed by a legal representative of a neonate. Anonymized observational data were provided to the authors of this study.

In total, we evaluated SpO₂ recordings from 42 patients divided into two categories: physiological neonates and pathological neonates. Twenty-one healthy physiological patients were term infants without any known pathology who were measured during the first hours after delivery. The recording time for each physiological patient was 3–21 h. Twenty-one pathological patients were premature (born before 28th week of gestation), with various diagnosed pathologies requiring oxygen support, most commonly bronchopulmonary dysplasia. The recording time for each pathological patient was 10–95 h. SpO₂ values were measured by Masimo Rad-97 pulse oximeter (Masimo Corporation, Irvine, CA, USA), with the sampling time set to 2 s and the averaging time set to 8 s.

2.2.1. Data Processing

The SpO₂ measurement noise was considered as a random process that affects the biased SpO₂ values at each time point. A noise-free SpO₂ value (SpO₂^{clear}) was estimated for each measured SpO₂ value (SpO₂^{meas}), and the difference of these parameters was considered as the noise component. The procedure of the noise estimation is shown in the flowchart in Figure 3 and is described in detail below.

Step 1: The unstable parts of the measured SpO₂ signal (SpO₂^{meas}), which were defined based on the study by Wellington et al. [31], were excluded from further processing. All SpO₂ values that met at least one of the following two criteria were excluded: (1) The SpO₂ value was measured at the time when the low-signal-quality alarm was triggered. The low-signal-quality alarm is a pulse oximeter indicator of potentially erroneous data; however, it does not guarantee the perfect quality of all other parts of the SpO₂ signal. (2) The SpO₂ value was the middle sample of a 30 s moving window in which SpO₂ changed by more than 10%. An example of the original raw SpO₂^{meas} signal with identified stable and unstable parts is shown in Figure 4. Step 2: All null or unavailable data points in the SpO₂^{meas} signal were replaced by the nearest preceding valid SpO₂ value. The replaced values were not included in calculations of the SpO₂ measurement noise. The aim of replacing the null and unavailable values was to avoid abrupt transitions to zero values in SpO₂^{meas}, while filtering the signal in the next step. Step 3: A median filter was applied to the preprocessed SpO₂ signal. This operation resulted in SpO₂^{clear} values that reflect SaO₂ values without the presence of any measurement noise. Step 4: Each SpO₂^{clear} datapoint was converted to an SaO₂ value, using an inverse function to the SaO₂–SpO₂ bias function. Each calculated SaO₂ value was then paired with the respective SpO₂^{meas} value of the raw data waveform. Steps 3 and 4 were repeated in case of the pathological patient data to find the optimal parameter values of the median filter, as described in the next section. Step 5: The differences, SpO₂^{meas} – SpO₂^{clear}, of all valid datapoints (i.e., all values that were not excluded in Step 1 or 2) pooled together from all patients were used for the statistical model of the SpO₂ measurement noise in the form of a cumulative distribution function.

Outliers larger than $\pm 6\%$ SpO_2 were excluded. We determined the SpO_2 measurement noise for two patient categories, physiological neonates and pathological neonates. Cumulative distribution functions were constructed for all SaO_2 values, for $SaO_2 \leq 96\%$, and for $SaO_2 \geq 97\%$.

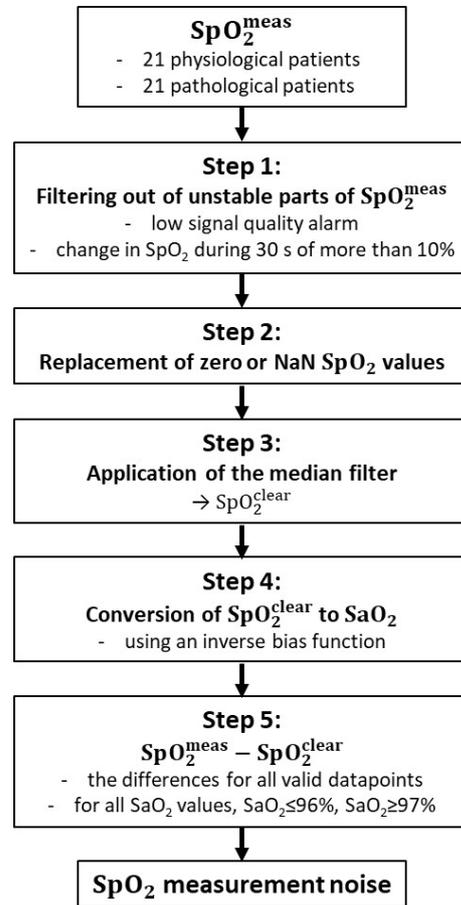

Figure 3. Data-processing flowchart for SpO_2 measurement noise estimation.

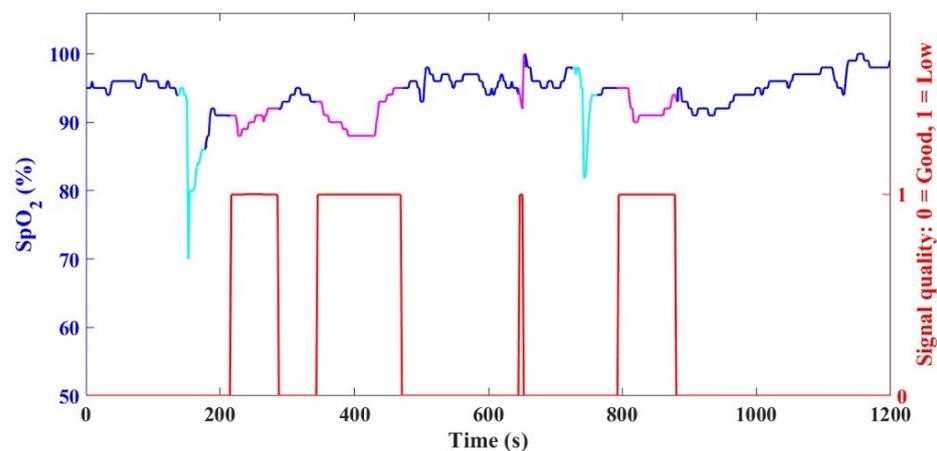

Figure 4. An example of the original raw SpO_2 data with stable parts (blue) and unstable parts (magenta and cyan). The stable parts were further processed to determine the noise, and the unstable parts were excluded due to the presence of the low-signal-quality alarm (red) or due to an abrupt change in SpO_2 (cyan) within a 30 s moving window.

2.2.2. Median Filter Window Size

At Step 3 of the SpO₂ measurement noise data processing, we applied the median filter to the SpO₂ signal to obtain noise-free SpO₂^{clear} values. The optimal median filter window size was determined from the comparison of the distribution of the SpO₂ recordings (for each SaO₂ unit) from 21 pathological patients and the distribution of the data acquired by Ross et al. [11]. An assumption for comparing the two datasets was the similarity of their noise characteristics, where both datasets were of pathological patients requiring ventilatory support who were less than 60 days old. Figure 5 compares the resulting SaO₂–SpO₂ data (generated based on the outcome of Step 4) with the data of Ross et al. [11]. For each SaO₂ unit, a histogram of the SpO₂ distribution of the calculated data was compared with the respective histogram of the data of Ross et al. [11]. The filter parameters that resulted in the best overlaps of these histograms were used to construct the cumulative distribution functions in Step 5.

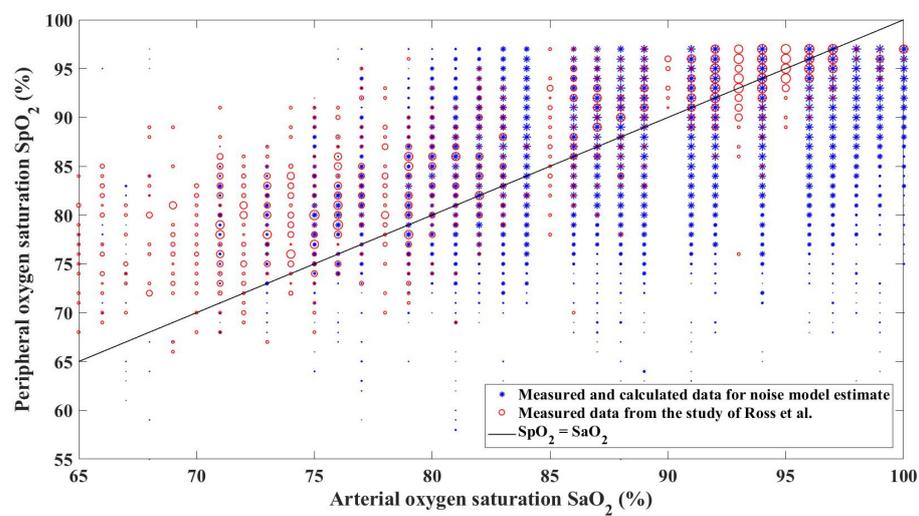

Figure 5. Comparison of SaO₂–SpO₂ scatterplots from the data for the noise model estimate and the data acquired by Ross et al. [11]. The diameter of a marker for each SaO₂–SpO₂ pair is proportional to the frequency of the value occurrence.

The optimal median filter window size was selected from the range 1–1000, as illustrated in Figure 6, so that it minimizes the cost function:

$$J = \frac{1}{m} \sum_{\text{SaO}_2=70}^{100} \left(1 - \sum_{(i)} \min \left[h_i(\text{SpO}_2^{\text{meas}}(\text{SaO}_2)), h_i(\text{SpO}_2^{\text{Ross}}(\text{SaO}_2)) \right] \right)$$

where h_i is the value of an i -th bin of a normalized histogram of the SpO₂ distribution, SpO₂^{Ross} refers to the data of Ross et al. [11], and m is the number of SaO₂ units for which both the SpO₂^{meas} data and SpO₂^{Ross} data are available for a particular filter window size. The J function evaluates the extent to which normalized histograms of the SpO₂ distributions overlap at each SaO₂ unit and was based on the histogram intersection measure [32]. If two histograms overlap perfectly, the value of the histogram intersection measure at the particular SaO₂ unit is 0. On the other hand, if the histograms do not overlap at all, the value is 1. An example of partially overlapping histograms for a single window size of the median filter is presented in Figure 7. The optimal median filter window size (WDW) was set to 227 samples, which corresponds to approximately 7.5 min of pulse oximeter output samples with the sampling time of 2 s.

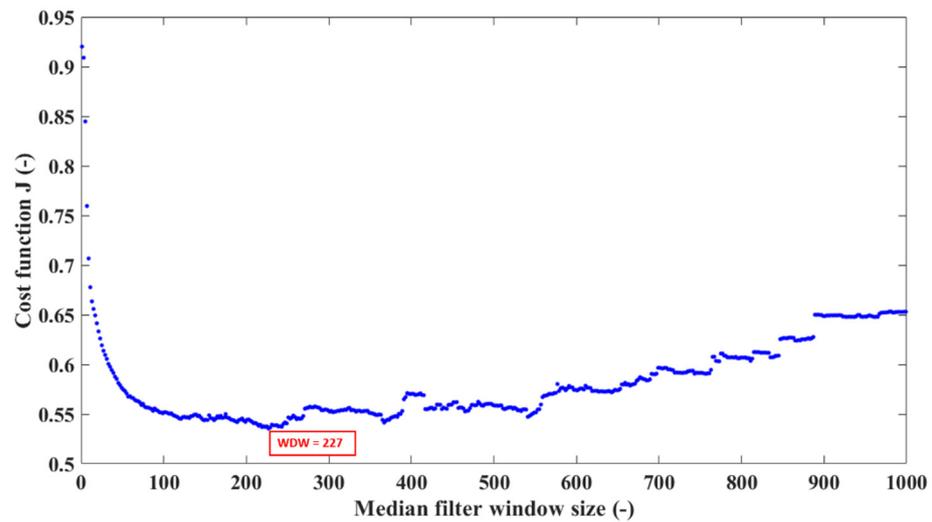

Figure 6. Estimating the optimal window size of the median filter by minimizing the cost function J . The optimal median filter window size (WDW) was 227 samples.

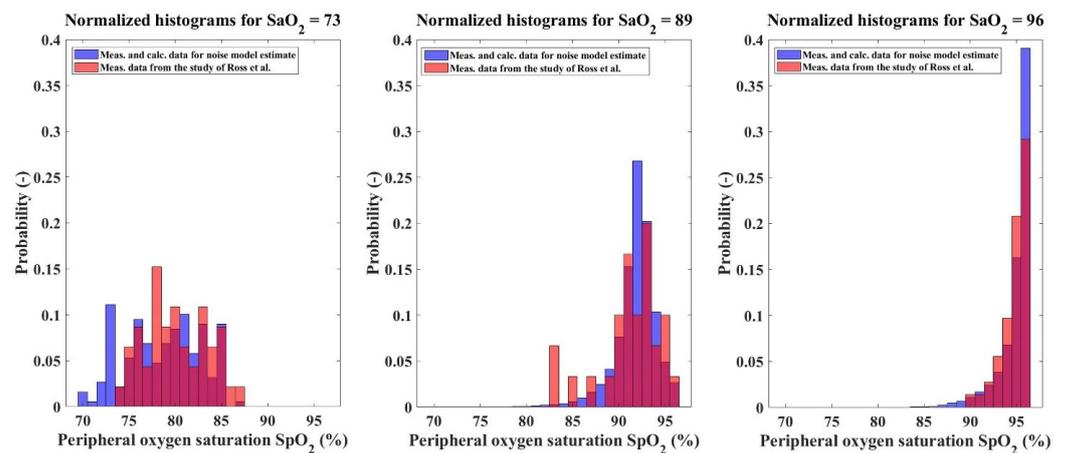

Figure 7. An example of partially overlapping histograms for three different SaO_2 units and the window size of the median filter set at 227 samples. The blue color represents the SpO_2 values measured to estimate the SpO_2 measurement noise. The red color represents the SpO_2 values acquired by Ross et al. [11]. The magenta color represents the histogram intersection.

2.2.3. Integration of SaO_2 – SpO_2 Bias with SpO_2 Measurement Noise

The pulse oximeter model, the terminal part of a complex mathematical model of neonatal oxygenation, integrates the SaO_2 – SpO_2 bias with the SpO_2 measurement noise. The input of the pulse oximeter model is the SaO_2 value. The input, sampled every 2 s, is converted to a noise-free SpO_2 value, using the SaO_2 – SpO_2 bias function. The output of the pulse oximeter model is then obtained by adding the SpO_2 measurement noise generated randomly, following the probabilities specified by the cumulative distribution function to the noise-free SpO_2 value.

3. Results

The model of the output of the pulse oximeter consists of two parts: the SaO_2 – SpO_2 bias and the SpO_2 measurement noise. The SaO_2 – SpO_2 bias function was determined in our previous study [30]. The SpO_2 measurement noise was estimated for two different groups of patients, physiological neonates and pathological neonates. Figure 8 depicts the resulting normalized histograms of the SpO_2 measurement noise for both the categories for all SaO_2 values and also separately for $\text{SaO}_2 \leq 96\%$ and for $\text{SaO}_2 \geq 97\%$. The statistical properties of the SpO_2 measurement noise are expressed by the cumulative distribution

function presented in Figure 9. The exact numerical values of the cumulative distribution function are provided in Appendix A in Table A1.

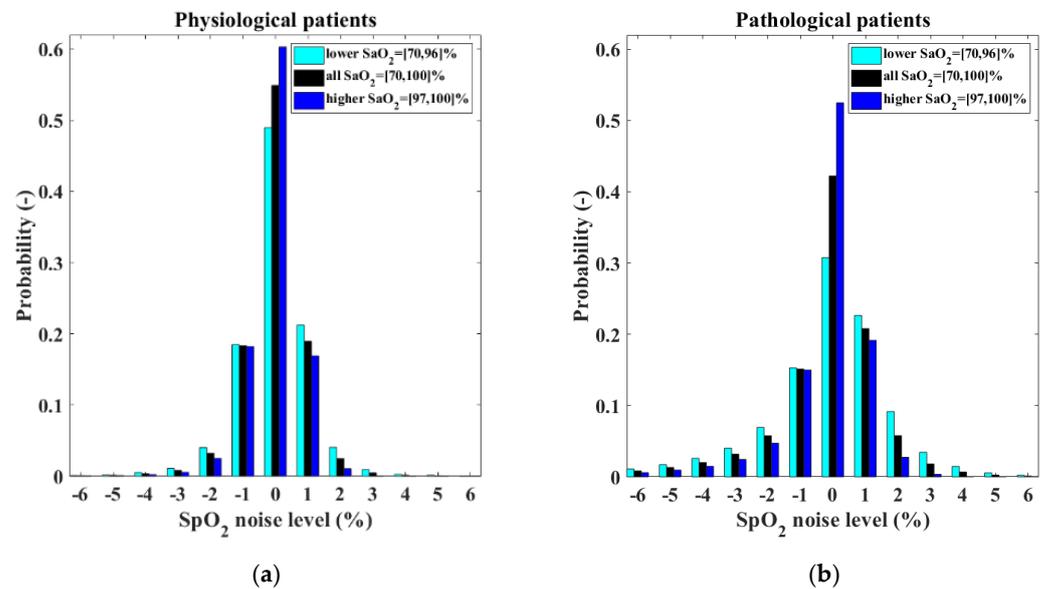

Figure 8. Normalized histograms of the SpO₂ measurement noise shows different characteristics for (a) physiological neonates and (b) pathological neonates.

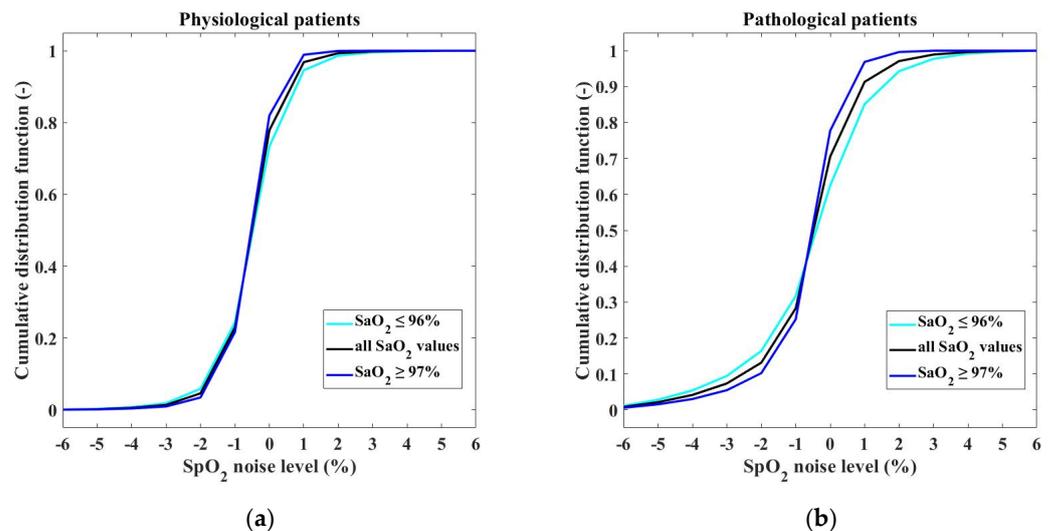

Figure 9. Cumulative distribution functions of the SpO₂ measurement noise for (a) physiological and (b) pathological patients.

In the pulse oximeter module, the random noise generated according to the characteristics presented in Figures 8 and 9 is added to the SpO₂ value calculated by using the SaO₂–SpO₂ bias function. Figure 10 shows the resulting SaO₂–SpO₂ scatterplot of the output of the pulse oximeter module. The figure displays the distribution of SpO₂ values generated for each SaO₂ value, including the frequency of occurrence of each SaO₂–SpO₂ pair.

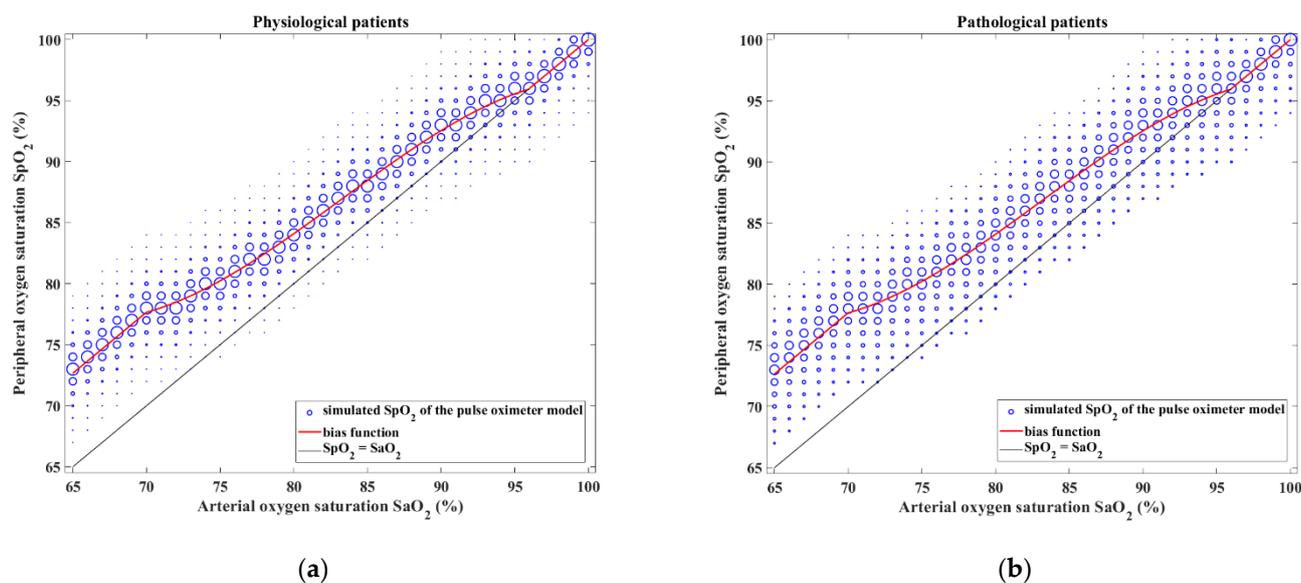

Figure 10. The output of the pulse oximeter model consisting of SaO₂–SpO₂ bias and SpO₂ measurement noise for (a) physiological and (b) pathological patients. Each SaO₂ value is converted to an SpO₂ value to which noise is added according to the properties shown in Figures 8 and 9. The size of the symbol of each SaO₂–SpO₂ pair is proportional to the frequency of its occurrence.

4. Discussion

In this work, we quantified the measurement noise that is characteristic for continuous SpO₂ time recording and completed the model of the output of the pulse oximeter typical for premature infants.

The model of the output of the pulse oximeter consists of two parts: the SaO₂–SpO₂ bias and the SpO₂ measurement noise. The SaO₂–SpO₂ bias was determined from the Ross’ clinical data [11] in the SaO₂ range of 70–100% in our previous study [30]. The bias values slightly differ between previously published clinical studies [11,14,18]. This may be due to different methods of measuring SaO₂ (co-oximetry vs. blood gas analysis), measuring SpO₂, or monitoring of the patients with different age and diagnoses. However, the published differences are too small to affect the credibility of the simulated output of the pulse oximeter model and its applicability to the neonatal oxygen transport model. For SaO₂ values less than 70%, the bias was held constant, equal to the value of the bias for 70% SaO₂ (7.66%), due to the lack of clinical data. The constant bias for SaO₂ of less than 70% would be a sufficient approximation for the model of a neonate on oxygen support, because these values are associated with severe hypoxemia and are beyond the target range in which the saturation of ventilated premature infants should be maintained. In addition, pulse oximeter manufacturers do not guarantee the accuracy of pulse oximeter measurements of such low saturation values [33].

In addition to the interpersonal variability of SaO₂–SpO₂ bias occurring in the studies [11,13–15,18] mentioned above, intrapersonal variability due to low perfusion, motion artifacts, or another noise, such as bright light or electromagnetic interference [21,23,24], also appears in the SpO₂ time recordings of each patient during the bed-side monitoring. In our work, we characterized the intrapersonal variability of SpO₂ time recording as the SpO₂ measurement noise. The noise was determined for two groups, physiological neonates and pathological neonates, based on the clinical data of 21 patients in each group as the difference between the measured SpO₂ values and the estimated SpO₂ values without noise. The noise model was estimated by using a numerical procedure in which the window size of the median filter was varied. The median filter was chosen over the moving average filter because of the frequent sudden but short drops in the SpO₂ signal (perhaps due to moving artifacts) that we wished to remove. The advantage of the median filter is its simplicity

and ease of implementation. However, other, more sophisticated denoising methods are available, based, for example, on wavelets [34] or compressed sensing [35]. The specific filter setting determined what would be considered a noise-free SpO₂ signal, thus indirectly generating variations of the noise model. We considered as the most plausible the variant of the noise model that produced our SpO₂ data distribution the most similar to that published by Ross in his study (as expressed by the minimum of the J function). The SpO₂ measurement noise was described by histograms and cumulative distribution functions not only for two categories of neonates but also for two different SaO₂ intervals, SaO₂ ≤ 96% and SaO₂ ≥ 97%. The boundary between the intervals was chosen to be identical to the intervals of the SaO₂–SpO₂ bias.

At the beginning of noise-signal processing, we excluded the unstable parts of the measured SpO₂ signal. The exclusion of all SpO₂ values measured during the episodes of triggered low-signal-quality alarm corresponds to automatic oxygenation control algorithms that do not consider such SpO₂ values reliable for automatic adjustment of the fraction of inspired oxygen [36]. In addition, all SpO₂ values that were the middle sample of a 30 s moving window in which SpO₂ changed by more than 10% were excluded. This second criterion was introduced because the distinct drops in the SpO₂ signal can be caused not only by artifacts but also by real desaturation, which cannot be distinguished without having the simultaneous data of the patient's movement available. Previous studies have considered motion artifacts as a major factor in inaccurate pulse oximeter readings [21,23], and this is even more influential in the group of preterm and term infants [37,38]. In comparison with adults, more motion, longer periods of motion, and more intensive motion were observed in infants [37]. Fletcher et al. [38] concluded that motion artifact can affect, overall, up to 50% of SpO₂ recorded time, and actually the motion artifact was present 91% of the monitored time during infant wakefulness. During the apnea, preterm infants can desaturate with a rate of 3–8% per second [39], and the study published by Poets and Southall [40] even reported the rate of up to 12.6% per second. Therefore, motion artifact and desaturation may have a similar SpO₂ recording, and motion artifact could be interpreted as the true desaturation and vice versa, or motion artifact can obscure the true desaturation with noise [23]. Abrupt changes in the SpO₂ signal due to desaturations are reflected in the pulse oximeter module, as they are generated by the overall model of neonatal oxygenation [8]. However, motion artifacts leading to significant drops in the SpO₂ signal (drops greater than 10% within 30 s) are not included in our model and should be modeled separately in a future study with simultaneous recording of SpO₂ signal and motion capture.

Our approach to the design of the pulse oximeter model can be compared with the model used by Morozoff et al. [29] in their physiological models. The main novelty of our model is that it is based on real clinical data measured on patients who are the target group for automatic control of oxygenation. The model incorporates the bias between SaO₂ and SpO₂, the presence of which is documented by many studies [11–19]. Furthermore, it proposes different noise levels according to the stability of the patients (physiological or pathological) and according to the input SaO₂ value, since, as the histograms in Figure 8 show, the noise distribution for low and high SaO₂ values is different.

The main limitations of the pulse oximeter model are the datasets used to determine the SaO₂–SpO₂ bias and SpO₂ measurement noise. One general SaO₂–SpO₂ bias function was based on the multicenter study on a relatively large number of patients from different PICUs, but the biases among children may systematically vary depending on its diagnosis [11,20], amount of fetal hemoglobin [11,14,20,22], or skin pigmentation [21,23]. The bias may also vary between different SpO₂ monitors or sensors [24], or between different sensor placements [15,20,21]. The noise model was determined based on comprehensive data from both physiological and pathological neonates; moreover, the amount of measured data allowed for the determination of noise characteristics for different SaO₂ intervals. The noise was estimated from the data measured at one setting of the pulse oximeter averaging time. The averaging time is usually adjustable in a range between 2 and 16 s and can significantly

affect the stability of pulse oximeter readings [33] and resulting noise characteristics. We determined the noise characteristic only for 8 s averaging (with an output update every 2 s), but it might be interesting to compare the noise characteristic of different averaging time settings. Moreover, the median filter we used for the noise estimation, as discussed above, may be disputed. Finally, due to the exclusion of the unstable parts of SpO₂ signal, our model of the SaO₂–SpO₂ relationship does not describe the effect of some motion artifacts that trigger the low-signal-quality alarm, as discussed in the previous paragraph.

The results of the work will improve the pulse oximeter model, which is the terminal part of the neonatal oxygen transport model, so that the simulated output of the model, the peripheral oxygen saturation, will more realistically represent the real SpO₂ signals observed in the clinical environment. This work and further improvements of the complex mathematical model will enhance the in silico testing and comparison of existing and future control algorithms under real clinical conditions. There is a need for improved modeling that reflects the dynamics of the neonatal oxygen transport system to achieve optimal control across the full spectrum of oxygenation disturbances, including the possibility of individualization of algorithm performance [10].

5. Conclusions

This work proposed methods for determining the measurement noise characteristics in peripheral oxygen saturation signal in combination with the bias between SaO₂ and SpO₂. The terminal part of the neonatal oxygen transport model, the pulse oximeter module, was improved in two ways: we determined the characteristics of the noise presented in SpO₂ time-recordings during the premature infant bedside monitoring, and we combined the SpO₂ measurement noise with SaO₂–SpO₂ bias. These results will improve the output of the neonatal oxygenation model and make simulations provided by the computer model of oxygenation of a neonate closer to the real situations observed in the clinical practice.

Author Contributions: V.R.-H., J.R., K.M. and T.E.B. conceptualized the research; T.E.B. and P.K. acquired the data; all authors contributed to the methodology of data analysis; V.R.-H. and J.R. performed data analysis, interpretation, and visualization; V.R.-H. and J.R. drafted the manuscript; K.M. and M.R. supervised the research. All authors reviewed and revised the manuscript. All authors have read and agreed to the published version of the manuscript.
