**Abstract:** The impact of deposition of multilayer CrN/CrCN coating on X6CrNiTi18-10 steel by means of the PVD (physical vapour deposition) method on resistance to cavitation erosion has been investigated. Cavitation tests were performed using a cavitation chamber with a barricade system at the inlet pressure  $p_1 = 600$  kPa and the outlet pressure  $p_2 = 123$  kPa. Deposition of CrN/CrCN coating allowed increasing duration of the incubation period and decreasing cumulative volume loss until 500 min of exposure. The erosion of the CrN/CrCN–X6CrNiTi18-10 system begins with the removal of microdroplets from the coating surface and surface undulation. The surface undulation increases with the exposure time leading to coating fracture in a brittle mode. Initiation sites of cracks were located inside the PVD coating. Measurements of surface roughness illustrate uneven degradation of the exposed surface and the location of slight and severe erosion zones. The Ra parameters obtained for the CrN/CrCN–X6CrNiTi18-10 system and X6CrNiTi18-10 steel after 180 min of erosion were comparable. An elongation of erosion test up to 600 min resulted in a higher increase in surface roughness of the CrN/CrCN coating–X6CrNiTi18-10 steel system in comparison to that of X6CrNiTi18-10 steel. With increasing exposition time, the rate of increase of the surface roughness decreased due to overlapping damage.

## 1. Introduction

Cavitation erosion is a serious problem of hydraulic equipment leading to a decrease of its efficiency and an increase in maintenance costs. For this reason, the design of hydrodynamic devices is modified to reduce the risk of cavitation erosion occurrence. However, complete elimination of cavitation erosion is not always possible. Hence, it is important to use erosion-resistant materials. Due to the limited applicability of the models developed so far, the selection of such materials is mainly based on experimental tests. In order to decrease the duration of the erosion tests, a specialist laboratory apparatus generates cavitation of high aggressiveness, e.g., a vibration testing device and cavitating jet apparatus [1]. Investigations performed in such laboratories have shown that implosions of cavitation bubbles cause materials to be subjected to high local compression followed by inertially driven tension [2]. Compressive strains of the order of 0.25 to 0.5 are localized on the area of  $0.18 \text{ mm}^2$  or less and act over a very short time period, less than  $24 \text{ }\mu\text{s}$  [2]. On the other side, investigations of Smith and Kinslow have shown that a rise time of pressure peak is approximately  $3 \text{ }\mu\text{s}$  and the decay time is of approximately  $5 \text{ }\mu\text{s}$  [3]. Bourne has found that a jet travelling at 400 m/s penetrates a solid

surface at a constant speed of approximately 200 m/s and the duration of the jet's impact is several  $\mu$ s [4]. These exceptional material loading conditions, i.e., very short impact time, and very high velocity and pressure of liquid jet penetration mean the experimental investigations in laboratories take several hours rather than several months or years. However, in real hydraulic equipment cavitation intensity is much lower than that in the laboratory test devices. For this reason, tests carried out with the use of apparatus enabling the regulation of cavitation intensity, in particular enabling tests at low cavitation intensity, are extremely desirable.

A material's resistance to cavitation erosion depends on its mechanical and endurance properties [5–8]. The most important ones are fatigue strength and hardness [8–12]. Therefore, technologies which allow increasing hardness, especially hardness of the surface layer, are used to improve the resistance of the material to cavitation erosion. Such technologies include modification of the surface layer by laser processing [13,14] as well as production of hard coatings [15–17]. Among the various technologies for the production of hard coatings, the PVD (physical vapour deposition) method arouses particular interest because it allows the deposition of coatings with special properties. The properties of PVD coatings depend on the deposited compound and its thickness in the monolayer coating or compounds, the number of layers, and their thickness forming the multilayer coating. In the case of nitride, carbon nitride and DLC (diamond-like carbon) coatings, PVD coatings are characterized by high hardness and Young's modulus, good wear and cavitation erosion resistance [18,19]. Despite hard coatings, the PVD method also allows high-reflection optical thin film to be produced, whose hardness is much lower than 1 GPa [20]. In the case of hard PVD coatings, their deposition can improve fatigue strength [21–23]. However, in some cases, especially when there is a big difference in hardness between the substrate and the coating, a decrease in fatigue strength is obtained [22,24]. An increase in hardness ( $H$ ) and Young's modulus ( $E$ ) lead to an increase in resistance to plastic deformation. As a measure of this resistance, the ratios of  $H/E$  (resistance to deformation relative to yielding) or  $H^3/E^2$  (resistance to the plastic indentation) are used [25,26]. By increasing these ratios, material stiffness increases.

Material endurance depends on deformation rate. The standard tests are performed at quasi-static conditions. However, under real conditions, the rate of deformation varies widely. With an increase in loading speed, the risk of rapid coating fracture increases. In the case of hard PVD coatings, e.g., nitride, oxides and DLC coatings, the risk of rapid degradation is related to their ability to withstand impact energy and a mode of crack development. This risk increases with increasing coating stiffness. According to [5,27], the impact velocity increases with increasing cavitation intensity. This promotes the development of a brittle fracture and results in a decrease in cavitation erosion resistance.

Due to high importance in potential applications of PVD coatings in hydraulic equipment, comparison of erosion resistance of PVD coatings obtained at various cavitation intensities is particularly significant. This article refers to a previous study [28], in which the cavitation erosion resistance of CrN/CrCN multilayer coating was investigated at the inlet pressure of 700 kPa and the outlet pressure 125 kPa. It was shown there that cavitation loading caused rapid degradation of this coating due to its low resistance to plastic deformation (high  $H/E$  ratio) and a brittle mode of the fractures.

The purpose of this article is to examine an effect of a decrease of cavitation intensity on the protective properties of the CrN/CrCN coating deposited on X6CrNiTi18-10 steel to cavitation erosion, especially on the incubation period duration and on the erosion rate. Because the inlet pressure affects cavitation intensity [29], the CrN/CrCN coating deposited on austenitic steel was tested at the inlet pressure of 600 kPa and the outlet pressure of 123 kPa. The results obtained were compared with those from [28]. Taking into account that cavitation intensity in hydraulic machinery is lower than in experimental investigations in laboratories, the aim of this paper is important for practical applications of a CrN/CrCN multilayer coating. In addition, the degradation process was investigated in detail, an in particular the state of the coating after 180 min of erosion was compared with the coating state after 600 min of erosion.

## 2. Experiment

### 2.1. Substrate

X6CrNiTi18-10 stainless steel has been used as a substrate. Before coating deposition, substrate specimens (45 mm × 26 mm × 14 mm) have been subjected to quenching at 1050 °C. The properties of X6CrNiTi18-10 stainless steel are presented in Table 1. Before the cavitation test, the specimens were mirror polished with diamond paste.

**Table 1.** Mechanical properties of X6CrNiTi18-10 steel.

Hardness [HRC]	Young's Modulus [GPa]	Ultimate Tensile Strength [MPa]	Yield Strength [MPa]	Elongation [%]	Density [g/cm <sup>3</sup> ]
25	199	662	307	36	7.86

### 2.2. Coating

The CrN/CrCN multilayer coating was deposited on X6CrNiTi18-10 stainless steel substrate by using the cathodic arc evaporation (CAE) method in the conventional multi-arc PVD system in the Koszalin University of Technology. The substrates were subjected to ultrasonic-aided cleaning with alkaline detergents, rinsed twice in deionized water and dried with compressed air. Next, they were placed in the vacuum chamber. The parameters of coating deposition are shown in Table 2. A pure (99.98%) chromium disc was used as a target material. Reaction gases, nitrogen and acetylene (for formation of the CrCN layer), were introduced near the cathode in order to increase the density of plasma. The CrCN/CrN coating was composed of six bi-layers with a single layer thickness ratio of 1:1. The flow rate of acetylene was matched to obtain 10 at.% of carbon content in the CrCN layer. In order to ensure proper adherence of the coating to the substrate, a thin chromium sub-layer of ~0.1 µm thick was initially deposited. The CrN and CrCN layers were deposited alternately, starting with the CrN layer. A top layer coating was the CrCN layer. The thicknesses of the CrN + CrCN bilayer (so called bilayer period) and the multilayer coating were determined using ball cratering test (Calotest) method. The thickness of the entire CrN/CrCN coating was  $4.3 \pm 0.2$  µm, while the thickness of the bilayer period was approximately 700 nm. According to [30], density of the coating is taken as 6.18 g/cm<sup>3</sup>. Some of the substrate specimens have been left uncoated, and later used as the reference ones.

**Table 2.** Deposition parameters of CrN/CrCN coating.

Pressure of Residual Gases	Working Pressure of Argon	Working Pressure of Nitrogen	Arc Current	Substrate Bias Voltage	Substrate Temperature
$1 \times 10^{-3}$ Pa	0.5 Pa	1.8 Pa	80 A	−70 V	300 °C

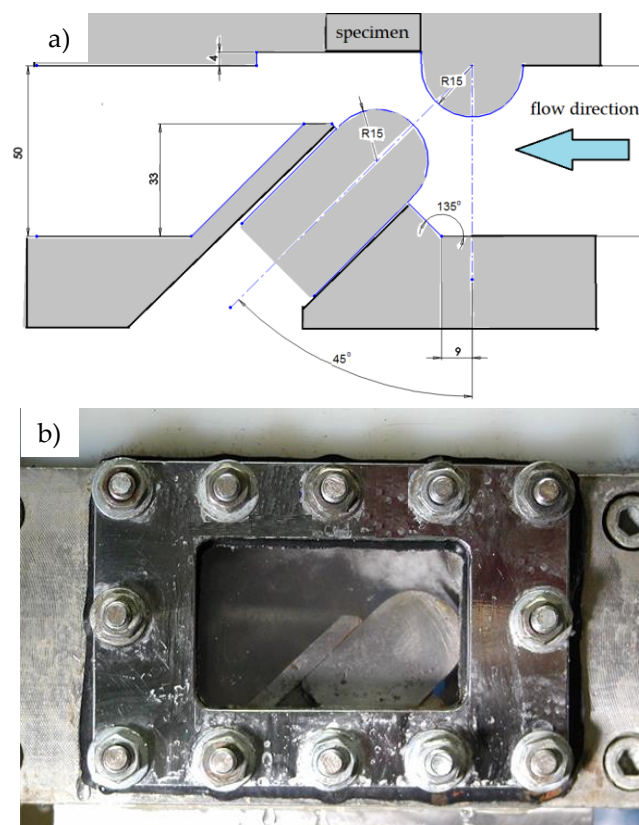

Hardness and Young's modulus were measured with a Hardness Tester Fischerscope HM2000 (Fischer Technology Inc., Windsor, CT, USA) equipped with Berkovich indenter. In order to eliminate an impact of the substrate on coating hardness measurements, the indentation depth must not exceed 10% of the entire coating thickness [31,32]. Due to the coating thickness of  $4.3 \pm 0.2$  µm, the maximum indentation depth of 300 nm has been applied. The hardness and Young's modulus of the CrN/CrCN multilayer coatings produced for current tests was  $24 \pm 2$  GPa and  $235 \pm 5$  GPa, respectively [28]. The properties of the multilayer coating depend on the properties of each layer, their thickness and the period of the bilayer module [19,33]. According to Reference [33], an increase in bi-layer module period caused initially also an increase in hardness and Young's modulus up to reaching the maximum values. A further increase in a module period was accompanied by a decrease in hardness and Young's modulus and after exceeding 150 nm of the module period, stabilisation values of hardness and

Young's modulus were observed. Taking into account that the module period in the tested coating was 700 nm, the values of hardness and Young's modulus were in a stabilisation regime.

Coating adhesion was measured using a scratch tester Revetest produced by CSEM. A diamond indenter with radius of 0.2 mm has been used. Measurements have been carried out at standard conditions: normal loading rate of 100 N/min, scratch speed of 10 mm/min and scratch length of 10 mm. For each specimen at least three scratches were caused. The adhesion was determined by observations from an optical microscope. First minor cracks occurred under the load of 4.7 N [28], which corresponds to the critical load  $L_{C1}$  defined by the occurrence of the first cohesive failure of the coating. The critical load  $L_{C2}$  related to the first delamination of the coating from the substrate and was used as a measure of coating adhesion was 29.8 N [28].

### 2.3. Cavitation Erosion Test

The cavitation erosion test was performed in the Institute of Fluid Flow Machinery Polish Academy of Science using a cavitation tunnel with a system of barricade/counter-barricade. The scheme of the tunnel and view of cavitation cloud are shown in Figure 1. The exact dimensions and full description of the cavitation tunnel have been presented in [26]. Flow conditions and cavitation intensity are controlled by inlet and outlet pressure. Specimens, both uncoated and coated, were subjected to cavitation loading at inlet pressure  $p_1 = 600$  kPa, outlet pressure  $p_2 = 123$  kPa, a slot width of 5 mm and using a 4 mm thick distance spacer. The applied inlet and outlet pressures resulted in a water flow velocity of 3.5 m/s in inlet pipeline and 35 m/s in the slot between the barricades. The temperature of the working liquid (tap water) was  $20 \pm 2$  °C.

**Figure 1.** Scheme of cavitation tunnel (a) and view of the testing part with cavitation cloud (b).

In order to observe the development of degradation of the tested specimens, the initial exposure interval lasted 5 min, then increased to 10 and then to 15 min for the first hour of the test. After that, the duration of exposure intervals increased to 30, 60, and 120 min. The total cavitation test lasted

600 min. Before the test and after each test interval, specimens were cleaned, dried and weighed using a first class analytical balance with sensitivity of 0.1 mg in order to achieve cavitation erosion curves.

#### 2.4. Roughness Measurements

Before the cavitation erosion tests and after 180 and 600 min of erosion tests, surface roughness was measured using the SJ-301 Mitutoyo Surface Roughness Tester. Roughness measurements were performed in the Institute of Fluid Flow Machinery at the Polish Academy of Science. Because of the flat surface of the specimens, only a few roughness measurements were performed. During the cavitation erosion test, due to variations in surface roughness depending on the distance from water inlet, the roughness measurements were performed along the mesh, as shown in Figure 2. Due to high sensitivity of the location of measurements, the measurements in the low eroded zone were performed three times while in the high eroded zones four times. For presentation of surface roughness, the  $R_a$  and  $R_z$  parameters were used. The  $R_a$  parameter is the arithmetical mean of the absolute values of the profile deviations from the mean line of the roughness. The  $R_z$  parameter is the average maximum peak to valley of five consecutive sampling lengths within the measuring length. Each value of roughness parameter was the arithmetic mean calculated from experimental data.

**Figure 2.** Mesh of the roughness measurements with marked eroded area.

#### 2.5. Microscopic Observations

After 180 and 600 min of erosion tests, microscopic observations of surfaces of eroded specimens and cross-sections were carried out in the Faculty of Mechanical Engineering, Gdansk University of Technology, using a scanning electron microscope (SEM) JEOL JSM-7800 F (Tokyo, Japan). The cross-sections were made on the basis of surface roughness measurements, i.e., the occurrence of high roughness, which was noted 3 mm from the water inlet (Figure 2).

### 3. Results and Discussion

#### 3.1. Cavitation Erosion Test

Because of high difference in density between the CrN/CrCN coating and X6CrNiTi18-10 steel, cavitation erosion curves are presented in Figure 3 in a form of volume loss vs. exposure time. Additionally, the curves of the erosion rate are presented in Figure 4, in order to better present the erosion process of the tested materials. In order to show the contribution of the CrN/CrCN coating to the degradation of the entire CrN/CrCN–X6CrNiTi18-10 system, the volume losses and the erosion rates of the coating and the entire system were shown separately. The volume losses were estimated based on observation of the damaged surface and determination of the corresponding coating mass.

**Figure 3.** Cavitation curves of X6CrNiTi18-10 steel and CrN/CrCN coating deposited on X6CrNiTi18-10 steel.

**Figure 4.** Curves of cavitation erosion rate of X6CrNiTi18-10 steel and CrN/CrCN coating deposited on X6CrNiTi18-10 steel.

According to Figure 3, an incubation period of the CrN/CrCN coating lasted 45 min in opposition to X6CrNiTi18-10 steel, which began to erode without an incubation period. The presence of the incubation period depends on material properties and cavitation aggressiveness. In the case of CrN/CrCN coating, the incubation period is associated with its high hardness and Young's modulus. Both of these properties affect critical stress to initiate fracture. In the case of X6CrNiTi18-10 steel, the aforementioned properties are much lower than those of the coating. The lack of an incubation period and mass loss together with the start of the cavitation erosion test indicate an aggressive cavitation flow for this steel. Similar results, including a lack of incubation period of X6CrNiTi18-10 steel, were also obtained in the previous investigations [28] and in Reference [34]. This indicates that a

decrease in the inlet pressure from 700 [28] to 600 kPa, in the present study, did not affect the initiation of erosion of this steel.

In the case of the CrN/CrCN–X6CrNiTi18–10 system, after the initiation period, a small loss of volume was noted in the 60th minute of the test (Figure 3). During the next 30 min of erosion, no volume loss was noted, up to 90 min of the test. After that, the volume loss of the CrN/CrCN coating increased much faster. Considering that on the surface of CrN/CrCN coating were micro droplets, that were generated during coating production [28], the initial loss of the coating was likely related to the removal of some of these droplets. This thesis is also confirmed by the temporary absence of volume loss up to 90 min of test. In addition, up to approximately 300 min of the cavitation erosion test, only the CrN/CrCN coating eroded. After that time, the substrate began to erode. Nevertheless, until 500 min of the cavitation erosion test, the cumulative volume loss of the entire CrN/CrCN–X6CrNiTi18–10 system was lower than that of the uncoated steel.

The CrN/CrCN coating belongs to hard and stiff coatings. Its resistance to deformation relative to yielding was the  $H/E = 0.102$ , while its resistance to the plastic indentation was the  $H^3/E^2 = 0.25$ . In the case of the steel substrate, the  $H/E$  and  $H^3/E^2$  ratios were 0.0085 and 0.00012, respectively. These two parameters show a high difference in stiffness between the coatings and the steel substrate. According to Reference [24], such a big difference in stiffness promotes a rapid fracture and a decrease in fatigue strength of the whole system. The performed investigations showed that despite the huge difference in deformation resistance, the deposited coating showed good protection of the ductile substrate against cavitation erosion.

Comparing the results obtained with the previous ones performed at  $p_1 = 700$  kPa [28], the reduction of the inlet pressure to  $p_1 = 600$  kPa in the cavitation erosion tests caused an extension of the incubation period from 30 to 45 min. Additionally, the volume loss of the CrN/CrCN–X6CrNiTi18–10 system decreased from 0.987 [28] to 0.755 mm<sup>3</sup> and the period, during which the volume loss of the system was lower than that of the X6CrNiTi18–10 steel, increased from 180 to 500 min, i.e., 2.78 times. This indicates that a decrease in inlet pressure caused an essential increase in the protection of X6CrNiTi18–10 steel by the deposited CrN/CrCN coating to cavitation erosion.

Curves of the cavitation erosion rate (Figure 4) show that erosion of the uncoated X6CrNiTi18–10 austenitic steel started with the highest erosion rate of  $0.0025 \pm 0.001$  mm<sup>3</sup>/min that then decreased nearly twice to  $0.0011 \pm 0.0002$  mm<sup>3</sup>/min reaching this value at 180 min of exposure. This decrease in erosion rate was likely associated with the  $Fe_\gamma \rightarrow Fe_\epsilon$  phase transformation, whose occurrence in austenitic stainless steels exposed to cavitation was confirmed many times, e.g., in [35–37]. The  $Fe_\gamma \rightarrow Fe_\epsilon$  phase transformation absorbs impact energy and causes an increase in surface hardness, so degradation becomes more difficult and more energy-consuming.

According to the ASTM G-32 standard, a typical cavitation erosion curve has 5 periods: incubation, acceleration, maximum rate value, deceleration and terminal stage, which is characterised by the final steady-stage erosion rate. In the investigations presented here, the degradation of the austenitic steel began at the highest rate (Figure 4), i.e., the third erosion period according to the ASTM G-32 standard. Then, the erosion rate decreased indicating on the deceleration period and finally the erosion rate became stable indicating on the terminal stage. Thus, referring to the ASTM G-32 standard, only three erosion periods were noted: the third erosion period at the beginning of the test followed by the fourth and fifth erosion periods. The duration of the deceleration period (a decrease in erosion rate) was likely related to the duration of the mentioned phase transformation. The final erosion rate of X6CrNiTi18–10 steel after 600 min of the test was  $0.0012 \pm 0.0001$  mm<sup>3</sup>/min.

In the case of the CrN/CrCN–X6CrNiTi18–10 system, after the incubation period, the erosion rate increased with the cavitation erosion test duration (Figure 4). The highest increase in erosion rate occurred from 90 to 180 min of exposure, when the erosion rate increased from  $0.0003 \pm 0.0001$  mm<sup>3</sup>/min to  $0.0008 \pm 0.0001$  mm<sup>3</sup>/min. It is worth mention that this erosion rate was caused by degradation of the CrN/CrCN coating. Because of the high  $H/E$  and  $H^3/E^2$  ratios of the coating, this coating is stiff and critical stress required to initiate fracture is also high. Therefore, the incubation period occurred.

However, after the initiation period, the cracks developed causing an increase in the erosion rate. Taking into account the high  $H/E$  and  $H^3/E^2$  ratios and a NaCl structure of CrN and CrCN, cracks developed in the coating in a brittle mode. From 240 min of the test, when substrate degradation began, the erosion rate of the whole system increased, but the erosion rate of the CrN/CrCN coating remained unchanged. The final erosion rate of the entire CrN/CrCN–X6CrNiTi18-10 system was  $0.00126 \pm 0.0001 \text{ mm}^3/\text{min}$ . Thus, the final erosion rate was close to that of uncoated steel.

Comparing the results obtained with the previous ones [28], the reduction of the inlet pressure from  $p_1 = 700 \text{ kPa}$  to  $p_1 = 600 \text{ kPa}$  caused a decrease in the final erosion rate of the CrN/CrCN–X6CrNiTi18-10 system from  $0.00165 \pm 0.0001 \text{ mm}^3/\text{min}$  to  $0.00126 \pm 0.0001 \text{ mm}^3/\text{min}$ . According to [29,38,39], the inlet pressure in the cavitation chamber affects the flow velocity and cavitation intensity. Thus, a decrease in the inlet pressure of only 100 kPa was sufficient to decrease the number of pulses and their impact speed, which resulted in a 24% decrease of the final erosion rate of the entire CrN/CrCN–X6CrNiTi18-10 system and approximately a 3-fold increase in duration of substrate protection by the CrN/CrCN coating. This shows that a slight change in cavitation intensity causes an essential impact on the protection properties of the CrN/CrCN coating against cavitation erosion. This sensitivity on cavitation intensity is caused by the large differences in plasticity parameters ( $H/E$  and  $H^3/E^2$  ratios) between the coating and the substrate. In the case of the  $H/E$  ratio, the difference was over 10 times, while in the case of the  $H^3/E^2$  ratio, the difference was over 2000 times. Nevertheless, considering that the cavitation intensity in real machines is lower than in laboratory devices and that the harder steel (e.g., martensitic steel) is often used as a substrate, this coating is expected to exhibit good protection against cavitation erosion.

### 3.2. Microscopic Observations

Microscopic observations of the eroded surface of the coating and the steel were carried out after 180 and 600 min of exposure. In Figure 5 is presented the eroded surface of X6CrNiTi18-10 steel, while in Figures 6 and 7 are presented surface and cross-sections of the CrN/CrCN coating–X6CrNiTi18-10 steel system after 180 min and in Figures 8 and 9 after 600 min, respectively.

During the first 180 min of test, austenitic stainless steel X6CrNiTi18-10 underwent plastic degradation with fatigue failure predominance (Figure 5a,b). Deformation twins covered with agglomerates of fatigue slip bands were formed (marked by a solid line). Slip bands were formed mainly in one direction which indicates an easy slip system. However, in some places, slip bands were formed in two slip systems (marked by a dotted line). Formation of slip bands in two intersecting slip systems indicates very high impact energy delivered. This is in agreement with volume loss (Figure 3). At some intrusions of slip bands cracks developed. This caused more intensive erosion of the steel surface, which led to the removal of surface particles (arrows in Figure 5b). In addition, pits of various diameters can be observed. Some pits were formed due to plastic deformation, as well as due to the removal of surface particles. Elongation of test duration to 600 min caused much more severe damage (Figure 5c,d). The surface is covered with high density of craters and cracks, which were formed in a ductile mode, typical for this steel. However, in less eroded zone, fragments of deformation twins and slip bands are still visible, and some extrusions of slip bands become crack initiators (Figure 5c).

Microscopic study showed that the volume loss of the CrN/CrCN coating–X6CrNiTi18-10 steel system that arose during 180 min of the test was mainly due to the removal of the micro-droplets that are formed during coating deposition (Figure 6a). This led to the formation of many tiny pits on the coating surface. These tiny pits were a source of crack initiation. In addition, Figure 6 shows that the surface underwent a slight micro-undulation that is confirmed on the cross-section in Figure 7. Cracks formed on the “tops” of the undulated coating migrated through these tiny pits (Figure 6a) from the top to the bottom of the undulated coating (Figure 7b). The height of the undulation is approximately  $5 \mu\text{m}$  (Figure 7a). In addition, Figure 7 shows that undulation of the coating–substrate system did not cause coating delamination. In addition, cracks developed mainly in the coating.

**Figure 5.** Eroded surface of X6CrNiTi18-10 steel; (a) and (b) after 180 min of exposition; (c) and (d) after 600 min of exposition.

**Figure 6.** CrN/CrCN coating - X6CrNiTi18-10 steel system after 180 min of exposition; (a) crack, (b) pit.

**Figure 7.** Cross-section of CrN/CrCN coating–X6CrNiTi18-10 steel system after 180 min of exposition; (a) undulation, (b) coating fracture.

**Figure 8.** CrN/CrCN coating–X6CrNiTi18-10 steel system after 600 min of test duration (a) pit, (b) eroded substrate.

**Figure 9.** Cross-section of CrN/CrCN coating–X6CrNiTi18-10 steel system after 600 min of exposition; (a) undulation in the lower eroded zone, (b) surface damage in the high eroded zone.

Undulation of the coating occurs as a result of ductile substrate undulation and causes an increase in stress level in the coating. The formation of cracks on the top of the undulated coating is mainly due to the high tensile stresses generated there. When tensile stresses exceed the local strength of the coating, cracks initiate. The presence of pits, which are the sites of stress concentration, additionally decreases coating toughness. According to the theory of contact stress, an impact generates shear stress below the exposed surface. The place of the highest shear stress depends on material properties, mainly elastic modulus. As the modulus of elasticity increases, the position of the maximum shear stress approaches the surface. On the other side, investigations of the development of stresses in a solid by a high-velocity impact [40] showed that the impact generates a compressive wave, which is followed by tensile reflection wave. As a result, compressive stresses are generated first, followed by tensile stresses. Thus, both of these phenomena promote the removal of micro-droplets.

Apart from tiny pits generated due to micro-droplets' removal, some pits were formed by impacts of micro-jets that were generated during the implosions of cavitation bubbles. An example of such pit is shown in Figure 6b. This pit has a shape of ellipse with one axis of about 70  $\mu\text{m}$  and second axis of about 50  $\mu\text{m}$ . However, the central depression has the diameter of about 16  $\mu\text{m}$ . Taking into account that a reflecting micro-jet also influences the pit diameter, the diameter of the micro-jet was likely about 16  $\mu\text{m}$ . The shape of this pit, especially its edge/rim, indicates high speed of the micro-jet and high local compressive stress, which led to shearing of the coating in a brittle mode and likely to a local temperature increase. In view of [41,42], heat is generated during the implosion of bubbles. An increase in temperature during micro-jet impact may additionally promote the formation of a pit.

Extending the test to 600 min contributed to development of coating erosion (Figures 8 and 9): an increase in substrate and coating undulation (Figure 9a), coating piercing (Figure 8a) and removal (Figures 8b and 9b) occurred. The height of coating-substrate system undulation increased to about 16  $\mu\text{m}$  (Figure 9a). Thus, during 420 min of the test (from 180 to 600 min) the height of undulation increased about 3 times. Such a big increase in coating undulation indicates very good adhesion and tensile strength of the coating. The increase in the undulation height increased stress level in the coating that promoted coating delamination. A high velocity micro-jet impacting in such a delaminated place punctured and pressed the coating into the substrate (Figure 8a). The diameter of damaged coating is about 35  $\mu\text{m}$ , but the central pit has one axis of about 10  $\mu\text{m}$  long and the second one of about 14  $\mu\text{m}$  long. The dimensions of damage are smaller than the dimensions of the pit shown in Figure 6b. However, the dimensions of the central pit from Figure 8a are comparable to the central depression from Figure 6b.

In some places in the area of the most aggressive cavitation pulses, the coating was removed revealing the substrate which underwent severe erosion (Figure 8b). On the surface were formed cracks, chips and craters. The depth of some craters was about 40  $\mu\text{m}$  (Figure 9b). The substrate fractured in a ductile mode typical for austenitic stainless steel (Figure 8b). This mode of fracture is better presented in Figure 9b.

Thus, elongation of the test led to increase in coating undulation, puncture and gradual removal, and finally substrate degradation. Considering the cavitation erosion rates of the CrN/CrCN–X6CrNiTi18-10 system and X6CrNiTi18-10 steel (Figure 4) and microscopic study (Figures 5–9), an increase in erosion rate of the CrN/CrCN–X6CrNiTi18-10 system after 240 min of the test was likely caused by simultaneously impacts of micro-jets and hard micro-particles of removed coating.

### 3.3. Roughness Measurements

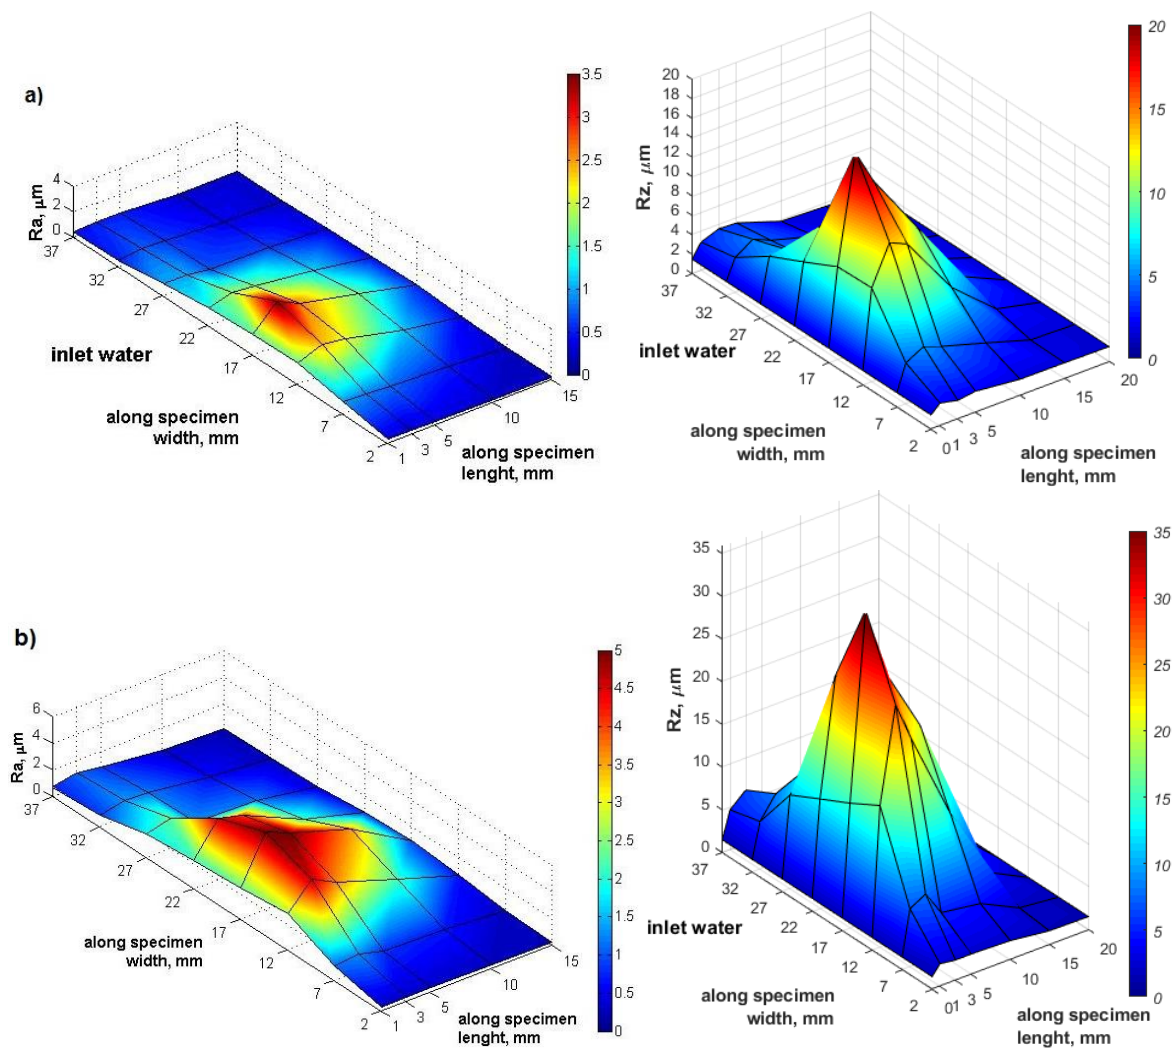

Initial surface roughness of X6CrNiTi18-10 steel was  $R_a = 0.09 \pm 0.08 \mu\text{m}$  and  $R_z = 0.67 \pm 0.5 \mu\text{m}$ , while for the CrN/CrCN coating was  $R_a = 0.26 \pm 0.07 \mu\text{m}$  and  $R_z = 2.52 \pm 0.47 \mu\text{m}$ . Higher surface roughness of the CrN/CrCN coating was caused by micro-droplets. The results of surface roughness measurements after 180 and 600 min of erosion of X6CrNiTi18-10 steel and the CrN/CrCN–X6CrNiTi18-10 system are shown in Figures 10 and 11, respectively. These graphs of the  $R_a$  and  $R_z$  parameter distributions show that higher roughness parameters were in the middle of the specimen width, approximately 17 mm of the specimen width, and near the sample front.

During an initial 180 min of erosion of X6CrNiTi18-10 steel, the  $R_a$  parameter increased up to  $R_a = 3.5 \pm 0.15 \mu\text{m}$ , while the  $R_z$  parameter increased up to  $R_z = 20.58 \pm 2.7 \mu\text{m}$  (Figure 10a). This increase in surface roughness was a result of slip bands, deformation twins, pits and craters, as is shown in Figure 5. In the case of the CrN/CrCN–X6CrNiTi18-10 system, cavitation action caused formation of the pits, as a result of the removal of micro-droplets and micro-jets impacts, micro undulation of the surface and the development of cracks (c.f. Figures 6 and 7). This led to an increase in surface roughness up to  $R_a = 3.78 \pm 0.2 \mu\text{m}$  and  $R_z = 20.39 \pm 2.5 \mu\text{m}$  (Figure 11a). The maximum roughness parameters of the CrN/CrCN–X6CrNiTi18-10 system were comparable to that of X6CrNiTi18-10 steel, despite different surface damages and the fact that the volume loss and erosion rate of the CrN/CrCN–

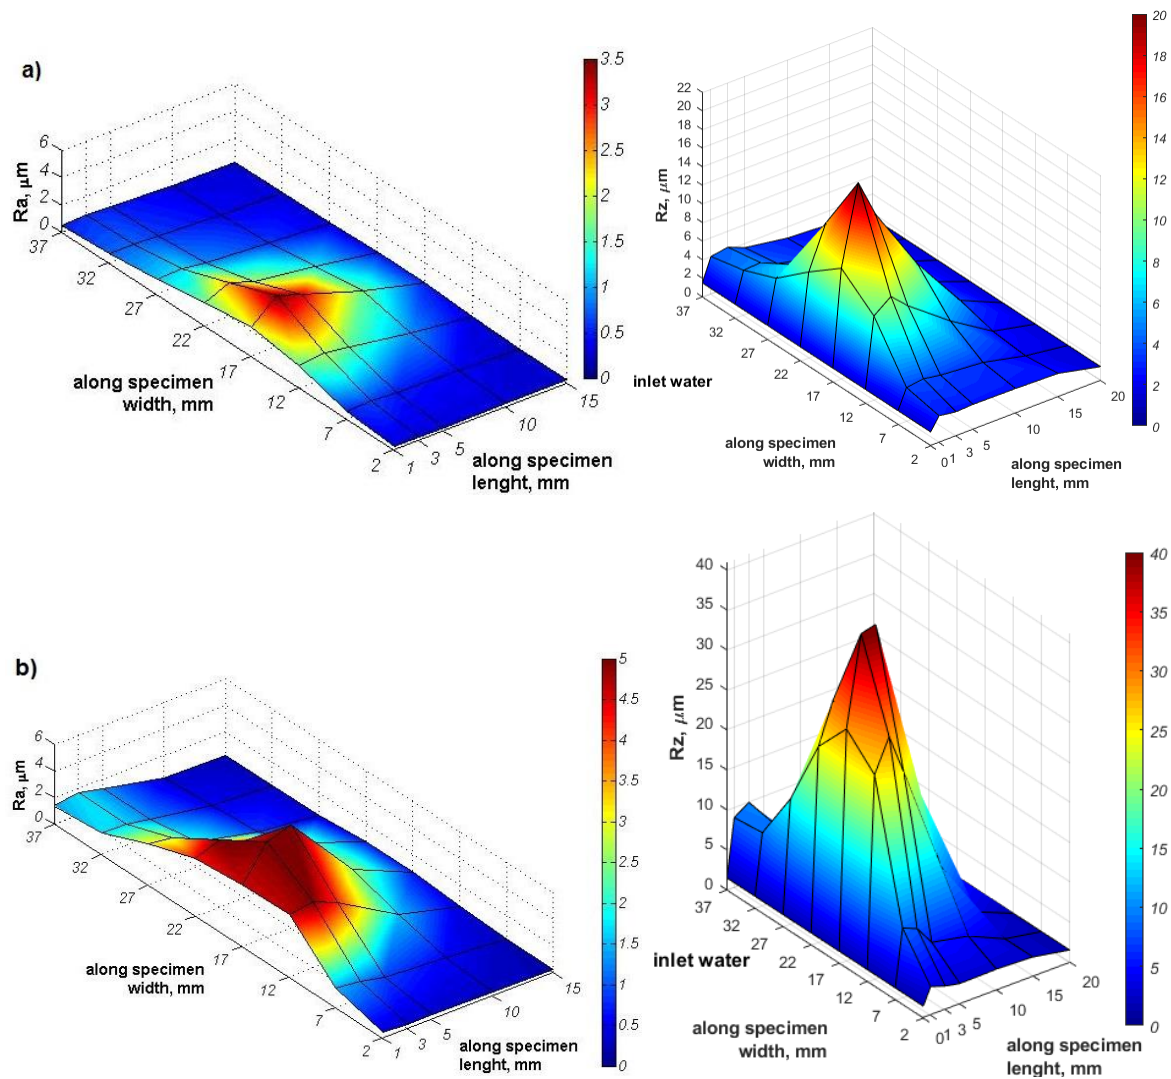

X6CrNiTi18-10 system were about 39% lower than those of X6CrNiTi18-10 steel (c.f. Figures 3 and 4). In addition, the roughness distribution throughout the eroded area is also comparable for both cases (Figures 10a and 11a).

Elongation of cavitation erosion tests up to 600 min caused a significant increase in surface degradation of the X6CrNiTi18-10 steel (Figure 5c,d) and the CrN/CrCN–X6CrNiTi18-10 system (Figures 8 and 9). Therefore, a high increase and different values of roughness parameters were expected. The performed measurements showed that the maximum value of  $R_a$  parameter increased up to  $5.86 \pm 0.56 \mu\text{m}$  and  $7.74 \pm 0.98 \mu\text{m}$ , respectively, for X6CrNiTi18-10 steel and the CrN/CrCN–X6CrNiTi18-10 system. In the case of the  $R_z$  parameter, it increased up to  $36.5 \pm 3.27 \mu\text{m}$  and  $40.6 \pm 2 \mu\text{m}$ , respectively for X6CrNiTi18-10 steel and the CrN/CrCN–X6CrNiTi18-10 system. The value of the maximum  $R_z$  parameter of the system was close to the crater depth shown in Figure 9b. Thus, the difference in surface roughness was caused by the number and depth of craters (cf. Figures 5, 8 and 9). The roughness distributions over the entire surfaces of X6CrNiTi18-10 steel after 600 min of erosion showed that a place of the highest roughness was unchanged in comparison to that after 180 min (Figure 10). In the case of the CrN/CrCN–X6CrNiTi18-10 system (Figure 11), this place was moved from the distance of 3 mm from water inlet (after 180 min) to 5 mm from the water inlet (after 600 min).

**Figure 10.** Distribution of  $R_a$  and  $R_z$  parameters on the surface of X6CrNiTi18-10 steel after (a) 180 and (b) 600 min of the cavitation erosion test.

**Figure 11.** Distribution of  $Ra$  parameter on the surface of the CrN/CrCN–X6CrNiTi18-10 system after (a) 180 and (b) 600 min of the cavitation erosion test.

Figures 10b and 11b show that the high roughness zone ( $Ra > 3 \mu\text{m}$ ) significantly increased at the specimen front, which is located next to the upper barricade (water inlet) and up to about 10 mm from the specimen length regardless of the tested material. The width of the high roughness zone varied depending on the examined material. In the case of X6CrNiTi18-10 steel, the high roughness zone starts from about 10 mm and ends at about 27 mm of the specimen width (Figure 10b). In the case of the CrN/CrCN–X6CrNiTi18-10 system, the high roughness zone starts at about 7 mm and ends at about 32 mm of the specimen width (Figure 11b). In addition, an area with  $Ra > 5 \mu\text{m}$  is essentially larger on the CrN/CrCN–X6CrNiTi18-10 system. Thus, high roughness area was bigger for the system, despite comparable volume loss. This was likely caused by system undulation, brittle fracture of the coating, and deep craters.

The roughness measurements of the CrN/CrCN–X6CrNiTi18-10 system and X6CrNiTi18-10 steel showed that during first 180 min of erosion, the  $Ra$  parameter increased at an average rate of  $0.021 \mu\text{m}/\text{min}$  and  $0.0194 \mu\text{m}/\text{min}$ , respectively. After the entire test (600 min), the average rate of a  $Ra$  parameter increase was  $0.0119 \mu\text{m}/\text{min}$  and  $0.0097 \mu\text{m}/\text{min}$ , respectively. In the case of the  $Rz$  parameter, during the first 180 min of erosion, it increased at an average rate of  $0.113$  and  $0.114 \mu\text{m}/\text{min}$ , and after the entire test, an average rate was  $0.0677$  and  $0.0608 \mu\text{m}/\text{min}$ , respectively. Thus, the average rates of an increase in roughness parameters decreased nearly twice. This indicates that surface roughness

increased with the highest rate at the beginning of the tests and with increasing test duration the rate of an increase in surface roughness decreased. This decrease in an increase in surface roughness is likely related to overlapping damage.

#### 4. Conclusions

The presented investigations of cavitation erosion resistance of the CrN/CrCN–X6CrNiTi18-10 system and X6CrNiTi18-10 steel performed at the inlet pressure of 600 kPa showed that:

- Deposition of CrN/CrCN coating on X6CrNiTi18-10 austenitic steel increased the incubation period and decreased cumulative volume loss. Until 300 min of erosion, only the coating in the CrN/CrCN–X6CrNiTi18-10 system was eroded. Starting from 500 min of erosion, the erosion rate of the system was comparable to austenitic steel.
- The decrease in the inlet pressure of 100 kPa resulted in a 24% decrease in final erosion rate and approximately a 3-fold increase in duration of substrate protection by the CrN/CrCN coating.
- Microscopic observations show that on the surface of X6CrNiTi18-10 steel were formed deformation twins covered by fatigue slip band agglomerates during the first 180 min of the test. Slip bands were formed mainly in the easy slip system, but in some places, slip bands were formed in two intersecting slip systems, indicating the very high impact energy delivered.
- Microscopic study of the CrN/CrCN coating–X6CrNiTi18-10 steel system showed the removal of the micro-droplets, formation of pits/craters by micro-jets, and system undulation during initial 180 min of the test. Cracks were formed on the tops of the undulated coating and developed along the pits after the removed micro-droplets, which decreased coating toughness.
- Extending the test duration to 600 min resulted in a 3-fold increase in the undulation height and the formation of craters about 40  $\mu\text{m}$  deep.
- After initial 180 min of the test, surface roughness of the coating ( $R_a = 3.78 \mu\text{m}$ ) was similar to that of the substrate ( $R_a = 3.5 \mu\text{m}$ ) despite different damage to the surface.
- The mechanisms of formation and development of surface damage were related to the ability to withstand plastic deformation. In the case of X6CrNiTi18-10 steel, an elongation of erosion test up to 600 min caused generation of pits and craters as well as the removal of surface particles. In the case of the CrN/CrCN coating–X6CrNiTi18-10 steel system, undulation of the surface increased and fractured in a brittle mode due to high  $H/E$  ratio. The coating was punctured and removed in some places by simultaneous impacts of micro-jets and hard micro-particles of the removed coating. The mechanisms of surface degradation affected a rate of change of surface roughness.
- At the beginning of the tests, surface roughness increased at the highest rate when the volume loss was very low and afterwards the rate of an increase in surface roughness decreased due to overlapping damage.
